Is there a relationship between environmental factors and pityriasis rosea? Reply to Singh et al.

Francesco Drago¹, Giulia Ciccarese¹✉, Aurora Parodi¹

To the Editor:

We read with great interest the article by Singh et al. on the relationship between environmental factors and pityriasis rosea (PR), and between PR and dengue virus (DENV) infection (1), which allows us to make some considerations.

In their retrospective study, the authors found temporal clusters of PR in the autumn and winter months, although not in all the years analyzed and with a statistically significant but weak correlation.

A higher prevalence of PR in cold seasons has been claimed (2, 3), but controversial opinions remain (4), mostly connected with the occurrence of the disease in clusters (5). In our experience, PR develops evenly distributed throughout the year (6). These differences may be due to the geographical areas where the various studies are performed. Notably, Singh et al. (1) examined an environmental factor greatly overlooked in previous studies; namely, the main total rainfall. They found that heavy rainfall is linked to a decreased incidence of PR, suggesting that this happens because the vector mosquitoes of dengue fever decrease their breeding during the period of heavy rainfall. Furthermore, in their PR patients they found a positive correlation with the presence of NS1 antigen or antibody positivity against DENV in their serum. Therefore, they suggest that DENV may be one of the etiological factors for PR (1). In this regard, some remarks should be made. The authors state that the average time between dengue fever and the onset of PR was over 78 days, and they mentioned a pair of twins for PR (1). In this regard, some remarks should be made. Data from studies on mediators in the sera of PR patients showed high levels of interferon alpha and gamma, fractalkine, and interleukin 22, in agreement with a cell-mediated immune response against microbial pathogens (11–13). Indeed, several studies have identified HHV-6 and HHV-7 systemic activation in PR patients, HHV-6 and HHV-7 DNA and HHV-6 viral messenger RNA expression by in situ hybridization, and HHV-6 and HHV-7 antigens in PR skin lesions (14, 15) converging fully with a productive viral infection and emphasizing the role of both viruses in the pathogenesis of the disease. Finally, to date, everything suggests a cell-mediated immune response against HHV-6 and/or HHV-7.
